

# Sternentstehung - Star Formation

Winter term 2015/2016

Henrik Beuther & Thomas Henning

13.10 Today: Introduction & Overview	(H.B.)
20.10 Physical processes I	(H.B.)
27.10 Physical processes II	(H.B.)
03.11 --	
10.11 Molecular clouds as birth places of stars	(H.B.)
17.11 Molecular clouds (cont.), Jeans Analysis	(T.H.)
24.11 Collapse models I	(T.H.)
01.12 Collapse models II	(T.H.)
<b>08.12 Protostellar evolution</b>	<b>(H.B.)</b>
15.12 Pre-main sequence evolution & outflows/jets	(H.B.)
22.12 Accretion disks I	(T.H.)
12.01 Accretion disks II	(T.H.)
19.01 Planet formation	(R.v.B.)
26.01 High-mass star formation, clusters and the IMF	(H.B.)
02.02 Examination week, no star formation lecture

# Topics today

- Infall signatures
- The first core and accretion luminosity
- The protostellar envelope structure
- Protostellar evolution

# Infall signatures I

Ovals are loci of constant line-of-sight for  $v(r) \propto r^{-0.5}$

From Evans 1999

1. Rising  $T_{\text{ex}}$  along line of sight
2. Velocity gradient
3. Line optically thick
4. An additional optically thin line peaks at center

# Infall signatures II

Models

Spectra and fits

(Myers et al. 1996)

In model with two uniform regions along the line of sight, with velocity dispersion  $\sigma$  and peak optical depth  $\tau_0 \rightarrow$  infall velocity  $v_{in}$ :

$$v_{in} \approx \sigma^2 / (v_{red} - v_{blue}) * \ln((1 + \exp(T_{BD}/T_D)) / (1 + \exp(T_{RD}/T_D)))$$

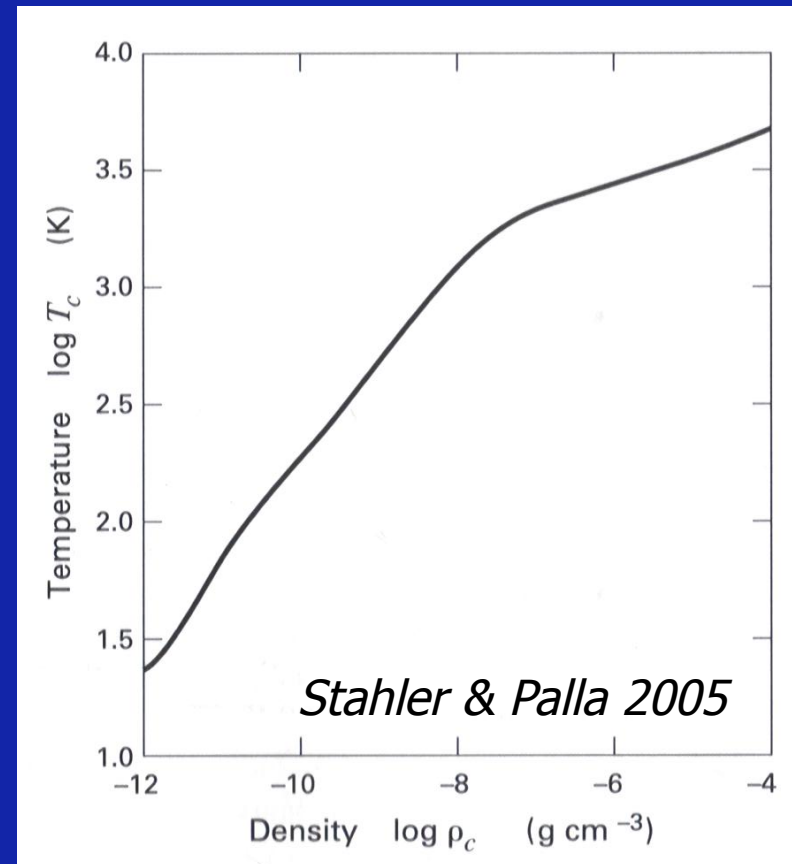

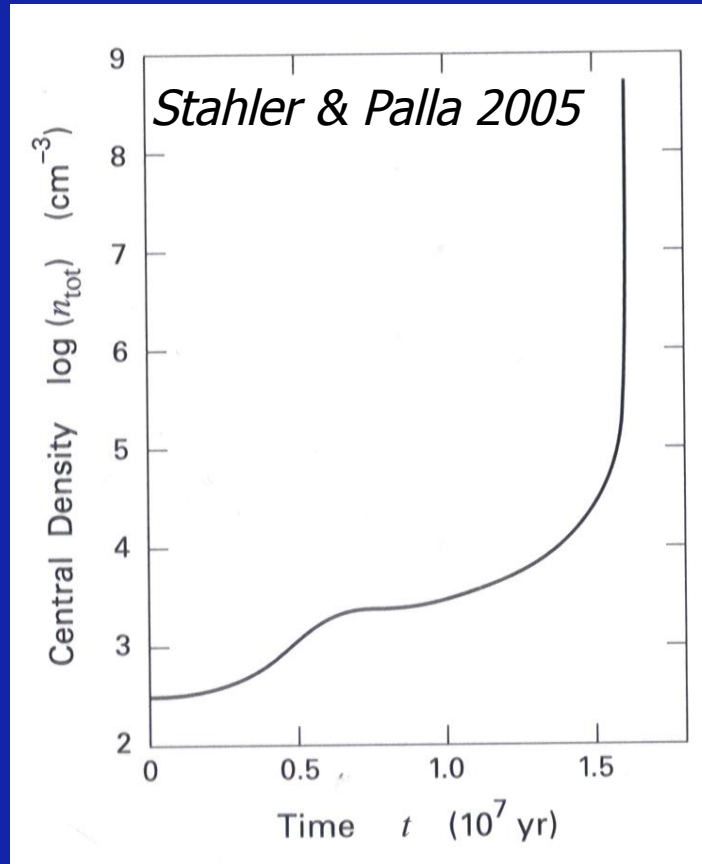

Low-mass regions  $\rightarrow v_{in}$  usually of the order 0.1 km/s.

High-mass regions  $\rightarrow V_{in}$  can exceed 1 km/s  $\rightarrow$  hence supersonic.

# Topics today

- Infall signatures
- The first core and accretion luminosity
- The protostellar envelope structure
- Protostellar evolution

# The first core I

- Contraction of core via ambipolar diffusion initially slow.
- $\Sigma/B$  reaches critical threshold  $\rightarrow$  contraction speeds up, high density  $\rightarrow$  core becomes opaque  $\rightarrow$  cooling less efficient  $\rightarrow$  T & P rise.
- Interior still mainly molecular hydrogen  $\rightarrow$  important for final collapse

# The first core II

- Temperature estimate based on virial theorem:

$$2T + 2U + W + M = 0$$

$$W = -2U$$

(kinetic & magnetic energy appr. as 0)

$$\Rightarrow -Gm^2/R = -3mRT/\mu$$

$$\Rightarrow T = \mu Gm/(3R R)$$

$$= 850K (m/0.05M_{\text{sun}}) (R/5\text{AU})^{-1}$$

→ significantly warmer than original core

- Addition of mass and further shrinking:
  - soon 2000K reached
  - collisional dissociation of  $\text{H}_2$  starts.

# The first core III

- However:

thermal energy per molecule at 2000K  
 $\sim 0.74\text{eV}$

compared to

dissociation energy of  $\text{H}_2$  of  $\sim 4.48\text{eV}$

- Even modest increase of dissociated  $\text{H}_2$  absorbs most grav. collapse energy
- marginal increase in T & P

- Region of atomic H spreads outward

- Without significant T & P increase, the first core cannot keep equilibrium
  - Entire core becomes unstable → collapses and forms protostar
  - significant T &  $\rho$  increase → collisionally ionize most hydrogen
  - emerging protostar is now dynamically stable.

- A protostar of  $0.1M_{\text{sun}}$  has radius of several  $R_{\text{sun}}$ ,  $T \sim 10^5\text{K}$  and  $\rho \sim 10^{-2}\text{g cm}^{-3}$

# Accretion shock and Accretion luminosity

- Grav. energy released during accretion approx. by the grav. pot.  $GM_*/R_*$   
 → accretion luminosity of protostar: energy multiplied by accretion rate:

$$L_{\text{acc}} = GM_*/R_* (dM/dt)$$

$$= 61L_{\text{sun}} ((dM/dt)/10^{-5}M_{\text{sun}}/\text{yr}) (M_*/1M_{\text{sun}}) (R_*/5R_{\text{sun}})^{-1}$$

- Additional luminosity from contraction and early nuclear fusion are negligible compare to  $L_{\text{acc}}$  for low- to intermediate-mass stars.
- **Conventional definition of (low-mass) protostar:**  
 "Mass-gaining star deriving most of its luminosity from accretion."  
 (However, caution for massive stars.)

# Topics today

- Infall signatures
- The first core and accretion luminosity
- The protostellar envelope structure
- Protostellar evolution

# Protostellar envelope I

- Outer envelope optically thin.
- Infalling gas compressed
  - protostellar rad. trapped by high dust opacities.
  - Dust reradiates at FIR
- Dust photosphere (a few AU for typical low-mass star) is effective warm radiating surface observable at MIR wavelengths

- Rapid T increase in dust envelope → dust sublimation at  $T \sim 1500\text{K}$ .
- Inside dust destruction front greatly reduced opacity
  - infalling gas transparent to protostellar radiation → opacity gap.
- Immediately outside the accretion shock, gas collisionally ionized
  - opacity increases again → so-called radiative precursor

# Protostellar envelope II

- Difference in radiation from shocked "radiative precursor" and far-infrared radiation from dust photosphere
- In shock region gas approaches protostar  $\sim$  at free-fall speed:

$$\begin{aligned}
 E_{\text{kin}} &= \frac{1}{2}mv_{\text{ff}}^2 = E_{\text{grav}} = GM_*m/R_* \\
 \Rightarrow v_{\text{ff}} &= \sqrt{2GM_*/R_*} \\
 &= 280 \text{ km/s} (M_*/1M_{\text{sun}})^{1/2} (R_*/5R_{\text{sun}})^{-1/2}
 \end{aligned}$$

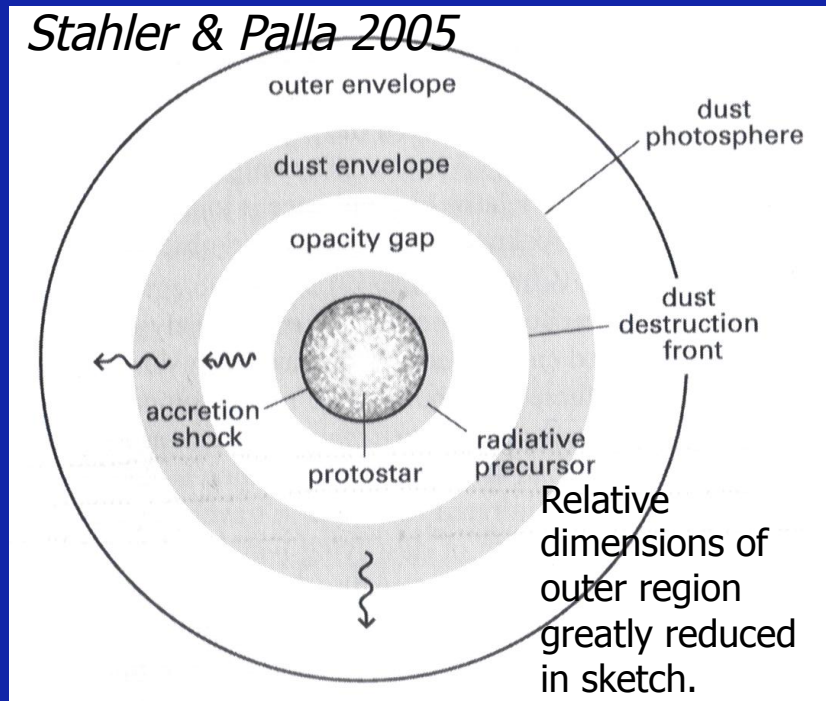

- Immediate postshock temperature  $> 10^6\text{K}$ , UV and X-ray regime
- Postshock settling region opaque, quick temperature decrease
- The surface of precursor radiates as  $\sim$  blackbody: Stephan-Boltzmann:

$$\begin{aligned}
 L_{\text{acc}} &\sim 4\pi R_*^2 \sigma_B T_{\text{eff}}^4 \quad \text{Substituting } L_{\text{acc}} \Rightarrow T_{\text{eff}} \sim (GM_*(dM/dt)/4\pi R_*^3 \sigma_B)^{1/4} \\
 \Rightarrow T_{\text{eff}} &\sim 7300\text{K} ((dM/dt)/1e-5M_{\text{sun}}\text{yr}^{-1}) (M_*/1M_{\text{sun}})^{1/4} (R_*/5R_{\text{sun}})^{-3/4}
 \end{aligned}$$

- Opacity gap is bathed in "optical emission" similar to main-sequence star. Very different to observable dust photosphere.

# Temperatures and dimensions of envelope

- Temperature profile in optically thick dust envelope  $T(r) \sim r^{-0.8}$
- Temperature profile in optically thin outer envelope  $T(r) \sim r^{-0.4}$
- Typical dimensions for a  $1M_{\text{sun}}$  protostar:
  - Outer envelope: a few 100 to a few 1000 or  $10^4$  AU
  - Dust photosphere:  $\sim 10$  AU
  - Dust destruction front:  $\sim 1$  AU
  - Protostar:  $\sim 5 R_{*} \sim 0.02$  AU

# Topics today

- Infall signatures
- The first core and accretion luminosity
- The protostellar envelope structure
- Protostellar evolution

# Protostellar evolution/Stellar Structure equations

- The protostellar evolution can be analyzed numerical similarly to stars.

→ Stellar Structure equations

- The used spatial variable is  $M_r$ , the mass within shells of radius  $r$

$$M_r = \int_0^r 4\pi r^2 \rho \, dr$$

$$\Rightarrow \partial r / \partial M_r = 1 / (4\pi r^2 \rho) \quad (1)$$

Hydrostatic equilibrium:  $-1/\rho \, \text{grad}(P) - \text{grad}(\Phi_g) = 0$

$$\Rightarrow \partial P / \partial r = -G\rho M_r / r^2 \quad (2)$$

Combining (1) in (2), one gets

$$\Rightarrow \partial P / \partial M_r = -GM_r / (4\pi r^4) \quad (3)$$

Pressure obeys ideal gas equation:  $P = \rho / \mu \, RT \quad (4)$

(mean molecular weight  $\mu$  depends on state of ionization and is function of  $T$  and  $\rho$ )

# Protostellar evolution/Stellar Structure equations

- Thermal structure of opaque interior is described by diffusion equation

$$T^3 \frac{\partial T}{\partial M_r} = - \frac{3\kappa L_{\text{int}}}{256\pi^2 \sigma_B r^4} \quad (5)$$

(mean opacity  $\kappa$  is again function of  $T$  and  $\rho$ )

- Spatial variation of internal luminosity  $L_{\text{int}}$  follows heat equation:

$$\frac{\partial L_{\text{int}}}{\partial M_r} = \varepsilon(\rho, T) - T \frac{\partial s}{\partial t} \quad (6)$$

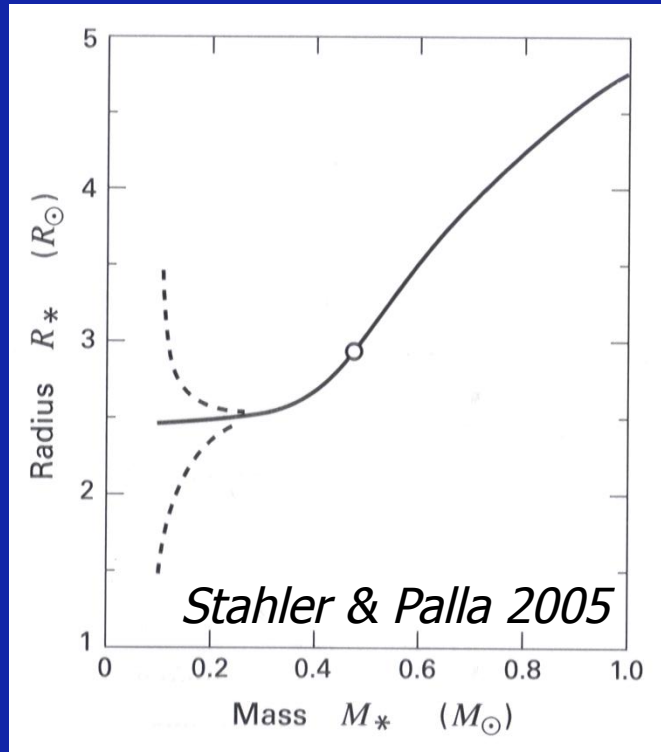

( $\varepsilon(\rho, T)$  rate of nuclear energy release;  $s(\rho, T)$  is the entropy)

(For a mono-atomic gas, the entropy is:  $s(\rho, T) = R/\mu \ln(T^{3/2}/\rho)$ )

- Using adequate boundary conditions, one can now follow numerically the protostellar evolution.

# Mass-radius relation

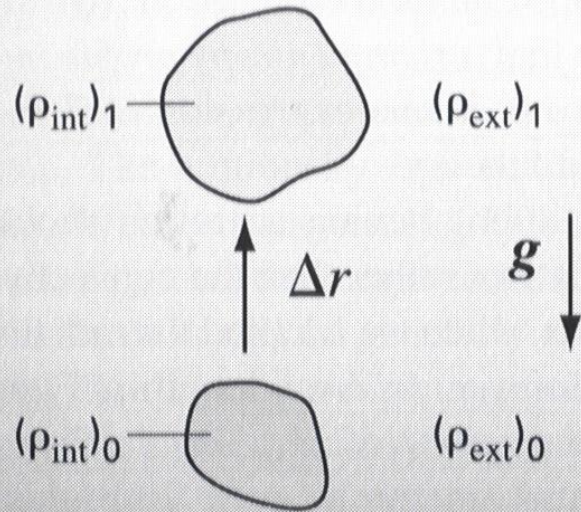

- Initial size unknown  $\rightarrow$  quickly converges
- Initially large  $\rightarrow$  low infall vel.  $\rightarrow$  low  $L_{\text{acc}}$   
 $\rightarrow$  low  $s(M_r)$   $\rightarrow$  initial decrease of  $R_*$
- Opposite effect for very small initial state.

- Adding additional infalling mass shells  
 $\rightarrow$  protostar can be described by entropy profile  $s(M_r)$   
(reflects conditions at accretion shock)

- $s$  represents heat content of each added mass shell  
 $\rightarrow$  increase of  $s(M_r)$  causes a swelling of the protostar.
- In the absence of nuclear burning, an increasing  $s(M_r)$  arises naturally because with rising  $M_*$ , the velocity of the infalling gas and hence the accretion shock and  $L_{\text{acc}}$  increases.  
 $\rightarrow$  Protostellar radius increases with time.

# Convection I

*Stahler & Palla 2005*

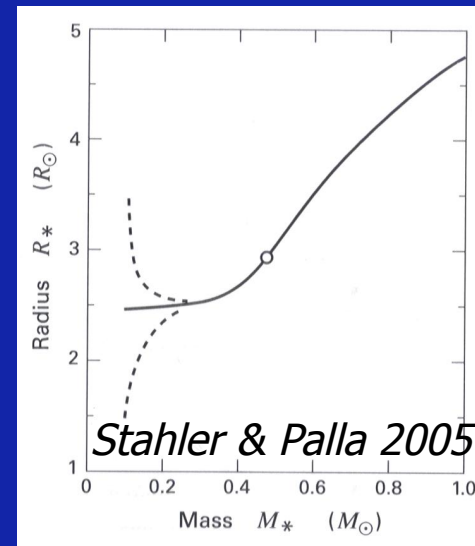

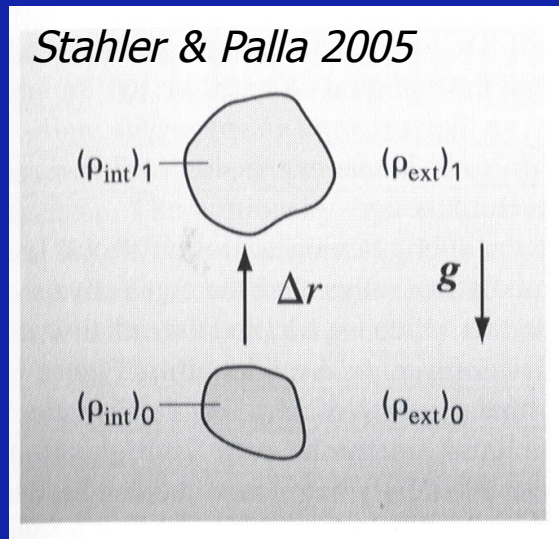

- Displace parcel outward.  $P_{\text{ext}}$  decreases.  
 $\rightarrow$  parcel expands and  $(\rho_{\text{int}})_1 < (\rho_{\text{int}})_0$

## - Question:

- If  $(\rho_{\text{int}})_1 < (\rho_{\text{ext}})_1$  parcel gets buoyant  
 $\rightarrow$  convection starts and becomes important for heat transfer.
- If  $(\rho_{\text{int}})_1 > (\rho_{\text{ext}})_1$  parcel sinks back down  
 $\rightarrow$  star remains radiatively stable.

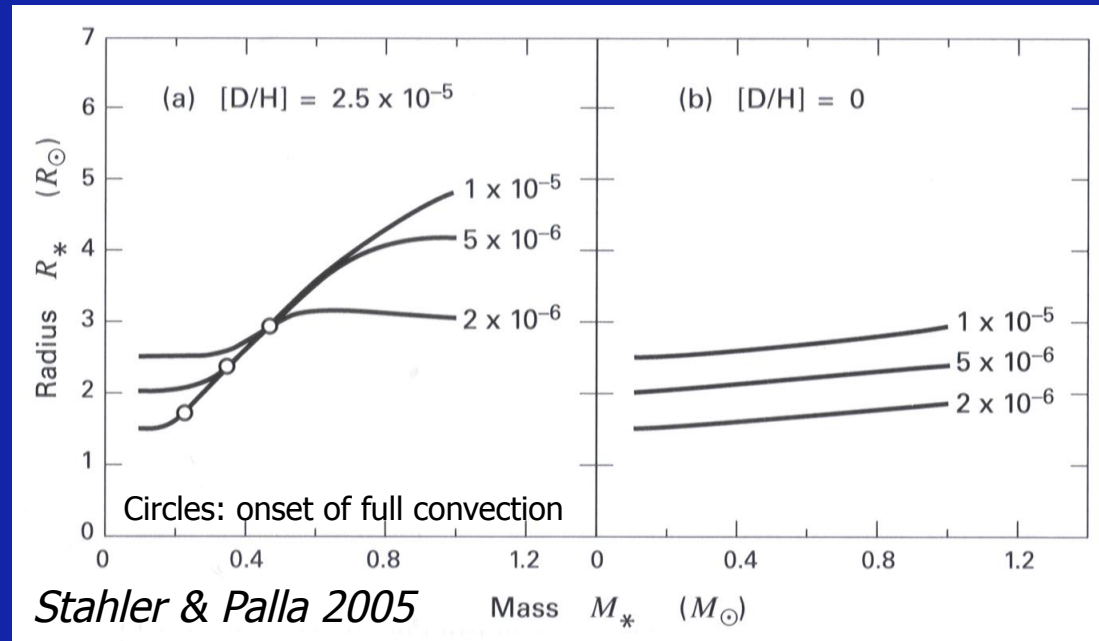

- If parcel displacement very quick  $\rightarrow$  heat loss is negligible  
 $\rightarrow$  its specific entropy  $s$  stays the same.
- In the absence of nuclear burning protostar has rising entropy profile  $s(M_r)$   
with  $\partial s / \partial M_r > 0$   $\rightarrow (s_{\text{int}})_0 = (s_{\text{int}})_1 < (s_{\text{ext}})_1$
- However,  $(P_{\text{int}})_1 = (P_{\text{ext}})_1$  and for ordinary gases  $(\partial \rho / \partial s)_p < 0$ ,  
i.e.  $\rightarrow$  density falls with increasing entropy at constant pressure.  
 $\rightarrow (\rho_{\text{int}})_1 > (\rho_{\text{ext}})_1$  for a rising entropy profile.  
 $\rightarrow \partial s / \partial M_r > 0$  implies radiative stability.

# Convection II

- However,  $M_*/R_*$  rises fast  $\rightarrow$  interior T increase  $\rightarrow$  Nuclear reactions start (at  $\sim 0.3M_{\text{sun}}$  deuterium burning at  $\sim 10^6\text{K}$ ).
  - $\rightarrow$  entropy profile turns  $\partial s/\partial M_r < 0$
  - $\rightarrow$  too much energy for radiative transport in opaque interior
  - $\rightarrow$  convection starts
- $\partial s/\partial M_r < 0 \rightarrow$  parcels are underdense ( $(\rho_{int})_1 < (\rho_{ext})_1$ ) and hot.
  - $\rightarrow$  heat transfer to surrounding  $\rightarrow$  denser/cooler parcels travel down again.
  - $\rightarrow$  Protostellar interior is well mixed and provides its own deuterium to center for further fusion processes.
- Convection is local phenomenon, some regions can be convective whereas others remain radiatively stable.

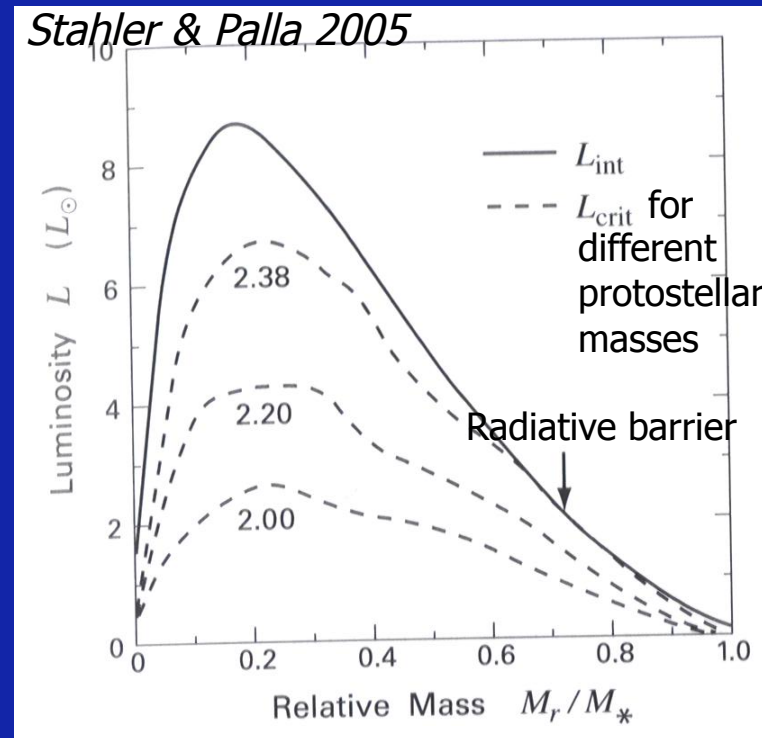

# Deuterium burning

- $2\text{H} + {}^1\text{H} \rightarrow {}^3\text{He} + \Delta E$  with  $\Delta E \sim 5.5$  MeV, important from  $10^6\text{K}$
- Protostellar size depends also on accretion but D-burning more important.
- The deuterium burning is very temperature sensitive:  
 Increase of  $T \rightarrow$  more deuterium burning  $\rightarrow$  more heat  
 $\rightarrow$  increase of protostellar radius ( $L_{\text{acc}} = G(dM/dt)M_*/R_*$ )  $\rightarrow$  lower  $T$  again  
 $\rightarrow$  Deuterium burning acts as kind of thermostat keeping protostellar core at that evolutionary stage at about  $10^6\text{K}$ .
- Steady supply by new Deuterium from infalling gas via convection necessary to maintain thermostat.

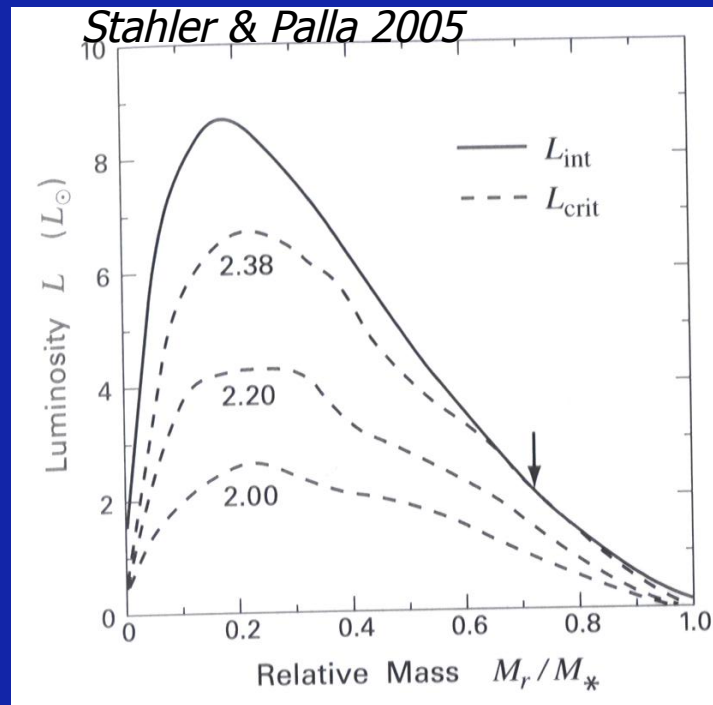

# Radiative stability again

What happens for Protostars gaining more than  $1-2M_{\text{sun}}$  of mass?

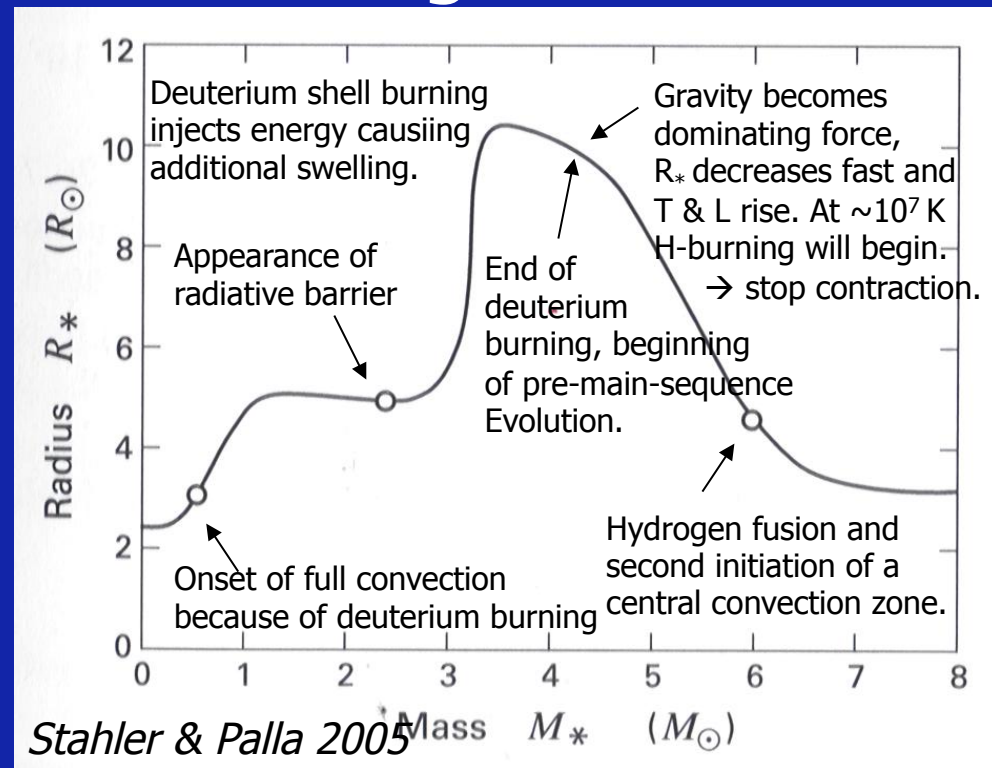

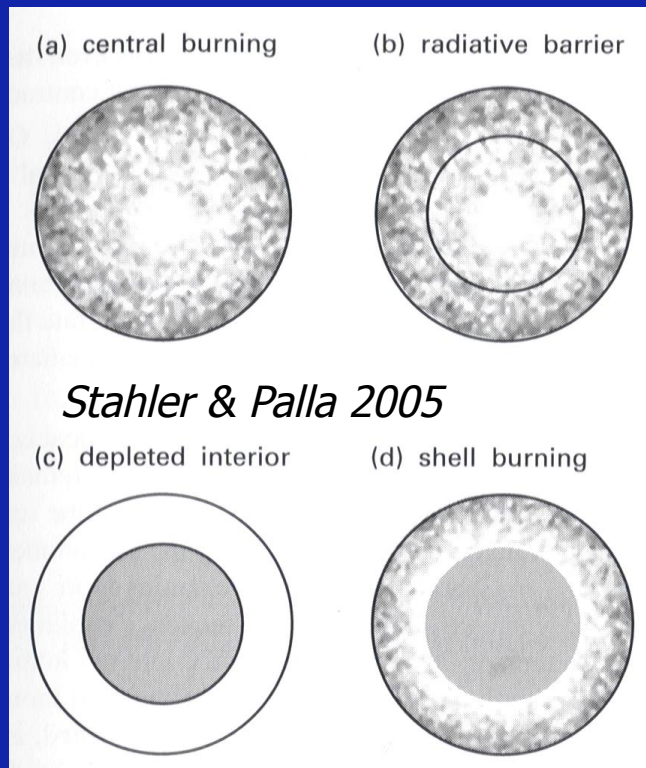

- The critical luminosity  $L_{\text{crit}}$  is the maximum value to be carried by radiative diffusion. It depends on opacity of gas/plasma.
- Continuum opacity from free-free emission (Kramers-law opacity) scales
$$\kappa_{\text{ff}} \propto \rho T^{-7/2} \rightarrow \text{strong decrease with } T$$
- And one finds:  $L_{\text{crit}} \propto M_*^{11/2} R_*^{-1/2}$ 
  - For growing protostars,  $L_{\text{crit}}$  rises sharply surpassing interior luminosity.
  - Convection then disappears and protostar gets radiative barrier.

# Deuterium shell burning I

- Radiative barrier  $\rightarrow$  no new deuterium to center & deut. consumed rapidly.
- Interior luminosity  $L_{\text{int}}$  declines below  $L_{\text{crit}}$   
 $\rightarrow$  convection disappears in whole interior volume.
- Deuterium accumulates in mantle outside radiative barrier.
- No internal fuel  $\rightarrow R_*$  does not change much anymore  
 $\rightarrow M_*/R_*$  rises more quickly, and temperatures increase rapidly.
- Base of deuterium shell reaches  $10^6\text{K}$ , deuterium shell burning starts and convection occurs in this shell structure.

# Deuterium shell burning II

- Deuterium shell burning is accompanied by structural change of protostar.
- The shell burning injects heat and rises the entropy  $s$  of the outer layers.
  - further swelling of the protostellar radius
- Adding even more mass, the inevitable rise of  $L_{\text{crit}}$  drives the radiative barrier and the associated burning layer and convection zone outward.
  - The protostar ( $> \sim 2M_{\text{sun}}$ ) is then almost fully radiatively stable.
- The previous scaling relation for  $L_{\text{crit}}$  should now apply to interior luminosity, and one finds:
 
$$L_{\text{int}} \sim 1L_{\text{sun}} (M_*/1M_{\text{sun}})^{11/2} (R_*/1R_{\text{sun}})^{-1/2}$$

# Summary

- The “first core” contracts until temperatures are able to dissociate  $H_2$  to H.
- H-region spreads outward, T and P not high enough to maintain equilibrium, further collapse until H gets collisionally ionized. The dynamically stable protostar has formed.
- Accretion luminosity. Definition of low-mass protostar can be “mass-gaining object where the luminosity is dominated by accretion”.
- Structure of the protostellar envelope.
- Stellar structure equations: follow numerically the protostellar and then later the pre-main sequence evolution.
- Convection and deuterium burning.

# Sternentstehung - Star Formation
